Lesson 1

Wrap Up C++

C++ language

Key features:

Compiled language

Multi-paradigm programming language:

Procedural

Object-oriented

Functional

Generic

Modular

Standardized

Language versions (according to standard):

C++98

C++03

C++07

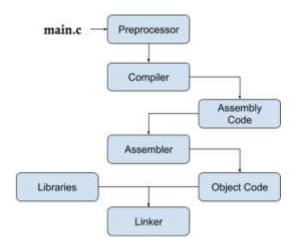

C++11

C++14

C++17

C++20

C++23

Program structure

- A program is a sequence of instructions
- A C++ program must have a main function.
- Before the program code, you can specify header files.
 Example: #include <iostream>
- Function body "is a sequence of instructions separated by a symbol;
- Usually, instructions are of three types: declaration, expression, control structure

```
#include <iostream>

int main () {
    std::cout << "Hello, World!" << std::endl;
    return 0;
}</pre>
```

Declarations

A declaration is a statement in two or three parts:

```
type identifier [= value or literal];
```

With a declaration, you can create a variable:

```
int x = 3;
```

Type:

- In C ++, the type system is strict. This means that every variable in your code has one well-defined type. In Python, for example, this is not the case.
- During the execution of your program, in the areas of RAM allocated for storing your local
 variables a new space of size corresponding to the size of the type of your variable is
 allocated in result of the declaration instruction.
- Each type has a numeric value called the size of the type, which indicates how much space variables of this type take up in RAM.

Fundamental types

C ++ has a specific set of built-in types:

char

- Integer variables: store only integer (possibly negative) values
- Real variables: store an arbitrary real number
- Boolean variables: store one of two possible values: true or false.
- Character variables: store an arbitrary character from an ASCII table (will discuss that later)

<pre>int unsigned long long unsigned long long</pre>	Size: 4 bytes. Stores integers in the range [-2 ^ 31, 2 ^ 31 - 1] Size: 4 bytes. Stores positive integers in the range [0, 2 ^ 32 - 1] Size: 8 bytes. Stores integers in the range [-2 ^ 63, 2 ^ 63 - 1] Size: 8 bytes. Stores positive integers in the range [0, 2 ^ 64 - 1]
float double long double	Size: 4 bytes. Stores an approximate value of a real number Size: 8 bytes. Stores an approximate value of the a number with double precision Size: 16 bytes. Stores an approximate value of the a number with 4x precision
bool	Size: 1 byte. Stores a Boolean value: true or false

Size: 1 byte. Stores a character from ASCII table

Identifiers

Any sequence of Latin letters, numbers and underscores that does not begin with a number and is not a **keyword** can be used as an identifier.

Example:

- a simple identifier
- x dir1

Keywords:

- if
- else
- for
- do
- while
- switch
- class
- ..

NON-Keywords:

- vector
- map
- cout
- cin
- endl
- list
- array
- •

Literals

A literal is a typed special value that can be used to initialize a variable. most primitive types have literals of their own.

Examples:

```
int
'a' char
true bool
false bool
"abc" string literal (will discuss later)
0.2f float literal
0.3 double literal
nullptr pointer literal (will discuss later)
```

Variable definitions with literals

Examples:

```
int x = 5;
bool y = true;
float z = 5.1f;
double k = 5.0;
long long p = 511;
unsigned long long q = 4ull;
```

Implicit type conversions

if you try to initialize a variable of a certain type with a certain literal of another type, in some cases it will work (and in some it will be an error).

Examples:

```
int x = 5.8;
bool y = 1;
float z = 5.1;
double k = 5;
```

Other examples of implicit conversions

bool <-> int implicit conversions:

```
bool -> int:
false -> 0
true -> 1

int -> bool:
0 -> false
Every other number -> true
```

<u>Rule</u>: when converting between types of different sizes, it is important to follow the rule: a number that can be converted to a specific type should not exceed the range of values of this type. Otherwise, a certain complex and ambiguous situation will occur, which is called overflow.

Some more examples of implicit type conversions:

```
'a' + 'b' -> int

5/3 -> int

division operator (will be discussed later) results in integer

int -> long long

int -> long long
```

Scopes

Each name that appears in a C++ program is only visible in some possibly discontiguous portion of the source code called its *scope*.

Within a scope, unqualified name lookup can be used to associate the name with its declaration. There are different kinds of scopes: block scope, function arguments scope, namespace scope, enumeration scope, class scope, etc. But today we will only talk about one of them: **block scope**.

Block scope

The potential scope of a name declared in a block (compound statement) begins at the point of declaration and ends at the end of the block. Actual scope is the same as potential scope unless an identical name is declared in a nested block, in which case the potential scope of the name in the nested block is excluded from the actual scope of the name in the enclosing block.

Scopes

One definition rule:

A variable with a certain identifier can only be defined once in a scope.

Error:

BUT this code is ok:

```
int main () {
    int x = 3;
    {
        int x = 4;
    }
}
```

Expressions

Most of a C ++ program is expressions.

An expression is some combination of literals and identifiers separated by operators.

Examples:

```
5 + x;
2;
++ y;
```

An **operator**, in computer programming, is a symbol that usually represents an action. These symbols were adapted from mathematics and logic. An operator is capable of manipulating a certain value or operand. For example, operator + has two operands and the result is the sum of the operands.

Operator **precedence** determines the grouping of terms in an expression: Within an expression, higher precedence operators will be evaluated first.

The **associativity** of an operator is a property that determines how operators of the same precedence are grouped in the absence of parentheses.

Lvalue and rvalue

Ivalue and rvalue in C++ 07:

If a value can be used as the left operand of the assignment operator, then it is called an **Ivalue**.

Otherwise, it is called an **rvalue**.

Note: In C++ 11 the value mechanism has been changed dramatically.

```
OK (x is an Ivalue):
int x = 3;
int y = 5; x = 7;
```

```
Incorrect (5 is an
rvalue):
int x = 3;
5 = x;
```

Operators

		Commo	n opera	tors		
assignment	increment decrement	arithmetic	logical	comparison	member access	other
a = b a += b a -= b a /= b a %= b a %= b a /= b a <<= b a >>= b	++a a a++ a	+a -a b b b b b b b b b b b b b b b b b b	!a a && b a b	a == b a != b a < b a >= b a <= b a >= b a <=> b	a[b] *a &a a->b a.b a->*b a.*b	a() a, b ?:
